

ABSTRACT

A method and apparatus for determining a user's Respiratory Quotient (RQ) using just measured O₂ and CO₂ concentrations without use of a flow meter. The RQ is determined by measuring the user's real-time inspired O₂ concentration (INS O₂) and end tidal O₂ concentration (ETO₂) and measuring the user's real-time inspired CO₂ concentration (INS CO₂) and end tidal CO₂ concentration (ETCO₂), and then determining the user's RQ from the measured INS O₂, ETO₂, INS CO₂, and ETCO₂ values in accordance with the following equation: $RQ = (ETCO_2 - INS\ CO_2) / (INS\ O_2 - ETO_2)$. In order to avoid error introduced by the flow rate, the measurement steps are preferably performed while the user is in a resting condition. Also, ETCO₂ is preferably measured as the maximum CO₂ value in a breath cycle of the user, while INS CO₂ is preferably measured as the minimum CO₂ value in a breath cycle of the user. Similarly, ETO₂ is preferably measured as the minimum O₂ value within a breath cycle of the user, while INS O₂ is measured as the maximum O₂ value within a breath cycle of the user. On the other hand, the values of INS CO₂ and ETCO₂ also may be determined in accordance with the invention by analysis of a CO₂ waveform of a breath cycle of the user and the values of INS O₂ and ETO₂ determined by synchronizing timing of the O₂ waveform of a breath cycle of the user with the CO₂ waveform and sampling INS O₂ and ETO₂ values simultaneously with sampling of complementary CO₂ values determined by analysis of the CO₂ waveform. The RQ measuring device may include the oxygen and CO₂ sensors in a mainstream or sidestream configuration.
